RESUME -This paper deals with the modeling of insulation material lifespan in a partial discharge regime. Accelerated aging tests are carried out to determine the lifespan of polyesterimide insulation films under different various stress conditions. The insulation lifespan logarithm is modeled as a function of different factors: the electrical stress logarithms and of an exponential form of the temperature. The model parameters, or so-called factor effects, is estimated on a training set. The significance of the factors is evaluated through the analysis of variance (ANOVA). In a first step, the design of experiment method (DoE) is considered. The associated lifespan model is linear with respect to the factors. This method is well-known for reducing the number of experiments while providing a good accuracy. In a second step, the response surface method (RSm) is considered. This method takes also into account some second order terms and thus possible interactions between the stress factors. Performance of the two methods are analyzed and compared on a test set.

Keywords— *dielectrics, insulation, accelerated aging, lifespan estimation, condition monitoring, modeling, response surface, analysis of variance, films, twisted pairs*

NOMENCLATURE

E_i	Effect of factor i
E_{ij}	Effect of interaction between factors i and j
y_i	Experimental value, measured at experiment i
F_i	Level of factor i , could be +1, -1 or any value between -1 and +1
M	Average experimental value
L	Lifespan (mn)
T	Temperature (°C)
V	Voltage (kV)
F	Frequency (kHz)
n	Number of experiments
P	Probability risk
N	Number of samples = number of repetitions

1. INTRODUCTION

Low voltage electric machines are increasingly submitted to heavy electric constraints and their lifespan becomes nowadays a great concern. Among many papers, [1] have reported that stator-winding insulation is one of the weakest components in a drive (around 40% of failures). Many operating factors such as voltage, frequency, temperature, pressure, etc. could have a dramatic effect, all the more that these stresses can interact between each other as shown in [2].

The existing models of degradation or of lifespan differs slightly from one paper to another but they are all based on physics and include some factors which are specific to the material or to the aging mechanism. As examples, [3]-[4] include the physical, thermal and electro-mechanical aspects of the electrical aging process. Additionally, the choice of the lifespan model as a function of these factors remains critical. Various models can be found in the literature (see [5] for instance). Most models involve a log-based relationship for frequency and voltage and an exponential form for the temperature. Nevertheless, there is no comprehensive model for insulation lifespan prediction under different combined stresses and this phenomenon remains complex and difficult to understand, especially with pulse width modulation (PWM) supply.

Experimental tests are required to assess lifespan modeling. However, full aging tests performed under nominal conditions and taking into account all the factors involved in the aging process, are of prohibitive cost. As a consequence, accelerated aging tests, which aim at speeding up the degradation, are generally performed. The objective is to predict the lifespan under nominal conditions from a model estimation in extreme conditions. The "Design of Experiments" (DoE) method [6] has been successfully used either for experiment optimization or modeling purposes. In the original method, a set of 8 experiments are carried out for each combination of the stress factors (Voltage, Temperature and Frequency). To be even more cost effective, this paper reduces the number of experiments. An Analysis of Variance (ANOVA) is then conducted to check the resulting model estimate validity.

Section 2 describes the studied materials and test bench and the state of the art DoE method. Section 3 presents factor significance analysis using ANOVA. Section 4 proposes response surface method for model improvement. Section 5 extends the study to the lifespan modeling of enamelled PEI-PAI wires. Conclusions and future works are discussed in section 6.

2. SYSTEM DESCRIPTION AND STATE-OF-THE-ART DOE METHOD

The test bench itself and the tested insulation materials have been fully described in [7]. The tested insulation materials consist of steel plates coated with polyesterimide (PEI - thermal class: 180°C) films which are widely used in rotating machine insulation systems (15cm x 9cm with a 90µm

coating). Moreover, twisted pairs (entwined copper cords, coated by an insulator varnish) are also studied while they are expected to behave similarly than the stator-winding insulator and are by far cheaper.

Fig. 1. Tested 90µm coated steel plate (15cm x 9cm)

Fig. 2. The experimental setup for accelerated

Accelerated Life Testing (ALT) is carried out, i.e. materials are submitted to extreme constraints to test their degradation without waiting until normal failure. The use of inverted-fed rotating machines enhances over-voltages and non-homogeneous voltages in the wiring. These heavy conditions can reach twice the nominal voltage just after the voltage application. Voltage and frequency are the main causes of the apparition of partial discharge (PD) into the isolator. PD can be defined as a localized dielectric breakdown of a small portion of a solid or fluid electrical insulation under high voltage stress. The discharge is said partial since it does not bridge the space between two conductors. In addition, several other factors can affect the insulation degradation such as temperature, depression, humidity, chemical or mechanical stresses. Furthermore, cycling some of these stresses can also impact the lifespan! Cycling can thus be considered as another degradation factor [3] [9].

The aging process is driven by several stresses acting simultaneously such as electrical, thermal, mechanical and ambient stresses. A review of the existing literature highlights four major factors affecting the lifespan: voltage amplitude (V) and frequency (F) of the supply periodic square waves, temperature (T) and temperature cycling. For simplicity and as a first modeling attempt, only the first three stresses are studied. Their extreme values are such that the insulation degradation is principally due to PD.

Eight samples were tested in our experimental setup, shown in Fig. 2. Under electrical stress, the steel plate acts as the first electrode and a spherical stainless steel electrode (diameter: 1mm) is the second. Samples were placed in a climatic chamber where the temperature is fully controlled. The lifespan of each sample was measured using a timer (one per sample) which stopped counting as soon as the measured current exceeded a predefined threshold corresponding to the sample break down. The faulty specimen was disconnected while the survivors remained under voltage and at the controlled temperature. Accelerated aging tests are carried out in order to relate the applied external stresses (factors) to the insulation lifespan (response). Lifespan data in this paper is presented according to the Weibull statistical distribution [9]. This distribution is commonly used for lifespan modeling. However, for simplicity and because of their influence, only three major parameters were studied :

- the square wave applied HVDC (V),
- the frequency of the applied voltage (F),
- temperature (T).

Their extreme and average values (the so-called levels of the considered modeling methods) are given in Table 1. According to [6], in the case of PEI material under PD regime, the insulation lifespan logarithm follows an inverse power model depending on $\log(V)$, $\log(F)$ and $\exp(-bT)$. Constant $b=5.64 \times 10^{-3}$ derives from calculations detailed in [6] from lifespan experimental results with respect to the temperature (for $V=2\text{kV}$ and $F=10\text{ kHz}$ i.e. at the center of the experimental domain).

Table 1 : levels of the three stress factors			
Factors	Level (-1)	Level (+1)	Level (0)
Log (Voltage (kV))	1	3	1.73
Log((Frequency (kHz))	5	15	8.7
Exp(-b.Temperature (°C))	-55	180b	26.7b

with $b= 5.64 \times 10^{-3}$

The first considered method for the PEI film lifespan modeling is the DoE method [11],[7]. The associated experimental plans and corresponding results are given in Table 2 and Table 3 for an easy understanding. Table 2 gives the 2^3 (3 factors, 2 levels each) possible combinations between the different factor levels. Note that the $N=8$ experiments have been performed with $k=8$ repetitions for each. Table 3 lists the associated measured lifespans (in minutes). The method models the lifespan logarithm as a function of the logarithms of the electrical stress (i.e. voltage

and frequency) and an exponential form of the temperature as expressed in (1). The estimated model coefficients are listed in Table 4 for films but the same kind of model holds for twisted pairs.

$$\begin{aligned} \text{Log}(L) \sim & M + E_V \cdot \text{log}(V) + E_F \cdot \text{log}(F) + E_T \cdot \exp(-bT) \\ & + E_{FV} \cdot \text{log}(V) \cdot \text{log}(F) + E_{VT} \cdot \text{log}(V) \cdot \exp(-bT) + \\ & E_{FT} \cdot \text{log}(F) \cdot \exp(-bT) + E_{VFT} \cdot \text{log}(V) \cdot \text{log}(F) \cdot \exp(-bT) \end{aligned} \quad (1)$$

The factor effects are derived using a simple matrix inversion. The corresponding results are given in Table 4 and Fig. 3. Once these factors have been derived, it is possible to evaluate their contribution to the model. The following section describes the ANOVA which is carried out to test the factor significance.

Factor	Effect
M	1.45
Log(V)	-0.53
Log(F)	-0.19
Exp(-bT)	-0.54
I _{Log(V),Log(F)}	-0.03
I _{Log(V),exp(-bT)}	0.12
I _{Log(F),exp(-bT)}	-0.03
I _{Log(F),Log(F),exp(-bT)}	-0.05

Fig. 3. Bar-graph representation of the factor effects

3. FACTOR SIGNIFICANCE ANALYSIS USING ANOVA

ANOVA is a widely used statistical method used to separate the total variability found within a data set into a random and a systematic contribution. It has been demonstrated in [9] that ANOVA is helpful in assessing the statistical significance of the different factor effects in many different applications, and in our concern in the field of electrical engineering. ANOVA is applied to the DoE results

described in section 2 in order to evaluate the significance of each factor. The normality of the distribution for each experiment is tested using a Shapiro-Wilk test and will not be described here. The independence of the measurements is ensured by the fact that each test has been realized independently on different coated steel plates.

DoE has been realized with 3 factors and 2 levels for each. $N=8$ ($=2^3$) experiments have been set with $k=8$ repetitions for each. The results obtained applying the ANOVA to the DoE is summed up in Table 5. It confirms that voltage and temperature are the two most significant factors. Consequently, their interaction is also significant. The effect of the frequency is significant but its interactions with other factors are not. Nevertheless, the interaction $I(V,F,T)$ is statistically significant according to ANOVA although its effect might seem low, $I(V,F)=-0.0506$. Accordingly, interaction effects between frequency and temperature, frequency and voltage, should not be taken into account in the ageing model. This method can also be used to predict how many repetitions are needed so a factor effect is significant.

Table 5: Significance of the DoE factors effects with $k=8$ repetitions

Factor	dof	Variance	$F_{exp}=V_i/V_r$	F_{lim}	Significant?
V	1	17.037	2218	4.00	Yes
F	1	2.3610	307	4.00	Yes
T	1	17.85	2324	4.00	Yes
V,F	1	0.021	2.7	4.00	No
V,T	1	0.329	42.8	4.00	Yes
F,T	1	0.017	2.2	4.00	No
V,F,T	1	0.123	16.0	4.00	Yes
Residues	56	0.0077			

4. RESPONSE SURFACE METHOD FORMODEL IMPROVEMENT

The DoE method is a regression method providing a model which can include some non-linear relationships between the stress variables. However, the resulting model only takes into account the factors (voltage V or temperature T for example) independently or products between them (VT). Some other effects such as the square of the voltage (V^2) could be influent as well and cannot be included in the DoE model. Response surface method (RSM) is a good candidate to complete the investigations and to provide extended models [12].

As in DoE, RSM organizes the experiments, minimizes their number and maximizes model accuracy. However, some central experiments (all levels equal to 0 when considering centered reduced variables) must be also tested to ensure certain properties. Consequently, the RSM design will have at least 3 levels, increasing the number of levels compared to DoE. Fortunately, experiments used in DoE can be reused in RSM.

Fig. 4. Graphic representation of the experimental points in a DoE (black) and in a CCD (in red)

The most popular design of RSM is the Central Composite Design (CCD) which considers an extra level α for several factors. The value of α is chosen to guarantee particular properties, such as listed in [13]. In this paper, to ensure the orthogonality property (with a number of 4 experiments in the center of the experimental domain), α must be equal to $\sqrt{2}$ as displayed in Fig. 4. Consequently, 5 levels $[-\sqrt{2}; -1; 0; +1; +\sqrt{2}]$ are chosen for each factor. The effect vector E can be computed like in the DoE method using expression (2):

$$\hat{E} = (X^t \cdot X)^{-1} \cdot X^t \cdot Y \quad (2)$$

In this paper, RSM is also used to improve lifespan modeling of the insulation of low voltage machines (films and enameled wires). A specific design is built in order to fit a second order model, (including the effect of V^2 for ex.), which means that the experimental surface is supposed to be fitted on a particular form. The method of least squares enables to estimate the regression coefficients in this multiple linear regression model. The response estimation, η , is then given by a second order polynomial, according to (3):

$$\eta = M + \sum_{i=1}^k E_i \cdot x_i + \sum_{i=1}^k E_{ii} \cdot x_i^2 + \sum_{i=1}^{k-1} \left(\sum_{j=i+1}^k E_{ij} \cdot x_i \cdot x_j \right) \quad (3)$$

Additional experiments inside the experimental domain are carried out in order to check the validity of the different models. Table 6 presents and compares the results obtained with different film lifespan models:

- DoE model has been built from 8 experiments focusing only on the main influential factors and interactions,
- SRM8 model relies on 8 experiments and includes only the most influential factors,
- SRM4 model is only based on 4 experiments randomly chosen out of the 8 experiments of SRM8 model and includes only the most influential factors.

It turns out in Table 6 that the use of the SRM significantly increases the model precision and that a reduction of the sample number (4 instead of 8) does not dramatically affect the model accuracy.

5. MODELING LIFESPAN OF WIRES

5.1. Models with DoE and RSM

This work also estimates the lifespan of motor wirings. In order to establish a lifespan model of the rotating electrical machine wiring insulation, the tested materials are twisted pairs covered with a double varnish of Poly-Ether-Imide (PEI) and Poly-Amide-Imide (PAI) with a thermal class of 200°C (Ederfil C200 with a diameter of 0,5mm), as shown in Fig. 5. Twisted pairs are manufactured according to the American National Standard (ANSI/NEMA MW 1000-2003, Revision 3, 2007). The varnish provides electrical insulation all along the surface without significantly increasing the volume or the weight. Electrical insulator varnish degrades across time and when submitted to electrical constraints. The insulator is designed to last for several thousand hours, but if the nominal constraints are over-passed the lifespan decreases dramatically.

It is well-known that PD appear into the insulation of rotating machines fed by inverters [4], [13], [14]. PD can be defined as a localized dielectric breakdown of a small portion of a solid or fluid electrical insulation under high voltage stress. The discharge is said partial since it does not bridge the space between two conductors. The insulation varnish is the first element in contact with PD and the most affected part of the insulation.

Fig. 5. Enameled wire PEI-PAI thermal class: 200°C

This study compares the models obtained with DoE, RSM and MLR. The experiments have been chosen in order to be used in the three methods. Experiments are organized as explained in the Table 7, where 30 experiments have been carried out. Some of them are used to estimate the wire lifespan model parameters whereas the others are used to test the model validity.

Table 7: Number of experiments vs identification method

DoE	8 exp.
RSM	8 from DoE+6exp.+4CP
Extra experiments	12 exp.

Thanks to DoE, the wire lifespan model M1 can be expressed as follows in (4) and (5):

$$\begin{aligned}
\log(L) \approx & M + E_V \cdot \log(10V) + E_F \cdot \log(F) \\
& + E_T \cdot \exp(-b \cdot T) + I_{VF} \cdot \log(10V) \cdot \log(F) \\
& + I_{VT} \cdot \log(10V) \cdot \exp(-b \cdot T) + \\
& I_{FT} \cdot \log(F) \cdot \exp(-b \cdot T) + \\
& I_{VFT} \cdot \log(10V) \cdot \log(F) \cdot \exp(-b \cdot T)
\end{aligned} \quad (4)$$

$$\begin{aligned}
\log(L) \approx & M + \sum E_i \cdot x_i + \sum I_{ij} \cdot x_i \cdot x_j \\
& + \sum I_{ijk} \cdot x_i \cdot x_j \cdot x_k
\end{aligned} \quad (5)$$

However, this model, estimated from 8 experiments only with DoE, when applied on twisted pairs, does not provide a very accurate lifespan prediction of the experiments composing the test set. The maximum error, derived from the test set and given in Table 8, is far too high.

Table 8: Relative errors between wire lifespan model M1 and the 12 extra experiments (long and short lifespan)

Average error	63%
Max. error	281.5%
Min. error	0.01%

In the case of RSM, the lifespan model M2 is the same as for DoE but with 3 extra squared terms (6).

$$\begin{aligned}
\log(L) \approx & Model_{DoE} + I_{VV} \cdot \log^2(10V) \\
& + I_{FF} \cdot \log^2(F) + I_{TT} \cdot \exp(-2b \cdot T)
\end{aligned} \quad (6)$$

In this case also, the model parameters (estimated from the 8 DoE experiments plus the 10 additional experiments needed for RSM) cannot be validated on the test set, as seen in Table 9 because of too large errors. The effects of the stress factors can be read in Fig 6, where several criteria are listed: average lifespan, median lifespan which could exclude outliers and average Weibull lifespan. The last form based on the Weibull distribution was finally chosen due to its wide use. Fig. 6 points out the most influential contributions on lifespan model i.e. Voltage, temperature and their interactions.

Fig. 6. Average effects of the stress factors with DoE and SRM on wire lifespans

Table 9: Relative errors between wire lifespan model M2 (SRM) and the 12 extra experiments (long and short lifespan)

Average error	51.4%
Max. error	483.1%
Min. error	0.8%

Obviously, mean errors are a little bit lower than for DoE but it is more important to notice that there is an aberrant lifespan with an absolute error of 483.1%. Once removed, the mean error decreases down to 37.5% and the max error to 150%. However, these results do not validate the lifespan model of the twisted pairs. In addition, studying the errors reveals that the biggest errors are always for very short lifespan. This fact seems to indicate a different degradation regime for short lifespan leading to a different model.

5.2. Models with Multiple Linear Regression (MLR)

DoE or RSM can be seen as regression methods taking into account nonlinear relationships between the stress variables. More generally, classical regression methods do not include any consideration on the experiment organization. The most common regression method is the linear regression. Nevertheless, as a multi-stress modeling problem is treated, simple linear regression cannot be used. The regression method that fits this problem is the multiple linear regression method (MLR) [15]. MLR performs the derivation of the least square estimator of the factor effects as follows in (7).

$$\hat{E} = (X^t \cdot X)^{-1} \cdot X^t \cdot Y \quad (7)$$

Calculations are similar to those of DoE or RSM but, in this case, the elements of matrix X are not normalized levels but the real value of each factor. Moreover, there is *a priori* no constraints for the choice of these experimental points. Multiple Linear Regression (MLR) will be the last studied method. First of all, in an attempt to compare the different methodologies, the model of equation (8) is first estimated from 11 randomly chosen experiments leading to the so-called model M3.

$$Y \approx \sum_{i=0}^{10} \hat{\beta}_i \cdot x_i \quad (8)$$

The β_i 's are the model parameters and the x_i 's are the real values of the so-called explanatory variables $M, \log(10V), \log(F), \exp(-bT), \log^2(10V)$, etc. in the same order than in the RSM model. As previously, lifespan depends on the factors and on their interactions. For comparison purpose, the same type of model is used than for the RSM. However, in the case of MLR, different expressions could have been chosen. The results show that the mean error is similar to those of RSM (38%) in Table 10. For performance improvement, the experiments corresponding to very short lifespan (less than 1.5 minutes) are removed and the number of experiments is increased. Indeed, small lifespan can be seen as outliers in the need for long lifespan models. Moreover, the MLR imposes no constraint on the experiment number and distribution, thus they can be chosen in particular ranges of interest. Estimation with 16 experiments and without the shortest lifespan generates a better model (M4) than before. From now on, all the errors in Table 11 remain lower than 55%.

Table 10: Relative errors between wire lifespan model M3 (MLR11) and the other experiments

Average error	38.1%
Max. error	150.4%
Min. error	0%

Table 11: Relative errors between wire lifespan model M4 (MLR16 without very the short lifespans) and the other experiments

Average error (Lifespan>1,5 min)	12.4%
Max. error	55%
Min. error	0.3%

Table 12: Relative errors between wire lifespan model M4 (MLR16 without very the short lifespans) and the other long lifespan experiments

Average error	5.3%
Max. error	29.7%
Min. error	0.1%

Consequently, it can be assumed that the very short lifespan do not follow the same model as long lifespan: a single model with a reasonable number of parameters is not sufficient to represent at the same time short and long lifespan. Thus, experiments corresponding to short lifespan must be removed for an accurate modeling of long lifespan. To check this hypothesis, lifespan lower than 3 minutes are also removed. The model is now estimated with 13 experiments only and tested on 6 experiments as in Table 12. In this case, the model estimation is particularly accurate.

6. CONCLUSIONS

This paper extended our previous work on lifespan modeling of the insulation of low voltage machines with the help of some statistical tools such as RSM and ANOVA. The most influential factors have been identified. It has been shown that the RSM increases modelling accuracy and that an experiment number reduction is possible with low risks.

Moreover, twisted pairs (entwined copper cords, coated by an insulator varnish) have also been studied while they are expected to behave similarly than the stator-winding insulator.

The analysis of the estimation performance on an appropriate test set has shown that the same model cannot simultaneously fit very short and long lifespan. It might be assumed that short lifespan (under 3 minutes) are due to phenomena that are not taken into account in the proposed models. Moreover, lifespan in twisted pairs are much shorter than in the steel plates insulated with PEI. Consequently, factor values must be chosen to avoid very short lifespan.

The ability of the DoE and the RSM to organize and to limit the number of experiments is confirmed. However, the models derived using these methods cannot benefit from additional randomly chosen experiments. From this point of view, MLR shows more flexibility. After a first analysis with the two first methods, regression can help to analyze different regions inside the studied domain and to eliminate outliers that might be due to defaults in materials or in the test bench.

Our objective is to extend the validity domain of the model, primarily towards low constraint levels, for prognostic purposes. Other constraints such as pressure will be included in future work.
